

ASSIGNMENT-7

Name:G.venkata Praveen

Reg.no:192373023

Dept:Cse(D.s)

1.Height of Binary Tree After Subtree Removal Queries

You are given the root of a binary tree with n nodes. Each node is assigned a unique value from 1 to n . You are also given an array queries of size m . You have to perform m independent queries on the tree where in the i th query you do the following:

- Remove the subtree rooted at the node with the value queries[i] from the tree. It is guaranteed that queries[i] will not be equal to the value of the root.

Return an array answer of size m where answer[i] is the height of the tree after performing the i th query.

Note:

- The queries are independent, so the tree returns to its initial state after each query.
- The height of a tree is the number of edges in the longest simple path from the root to some node in the tree.

Program:

```

class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

def height(root):
    if not root:
        return 0
    return 1 + max(height(root.left), height(root.right))

def removeSubtree(root, target):
    if not root:
        return None
    if root.val == target:
        return None
    root.left = removeSubtree(root.left, target)
    root.right = removeSubtree(root.right, target)
    return root

def heightAfterSubtreeRemoval(root, queries):
    result = []
    for query in queries:
        root = removeSubtree(root, query)
        result.append(height(root))
    return result

# Example Usage
# Construct the binary tree
root = TreeNode(1)
root.left = TreeNode(2)
root.right = TreeNode(3)
root.left.left = TreeNode(4)
root.left.right = TreeNode(5)
root.right.left = TreeNode(6)
root.right.right = TreeNode(7)

queries = [3, 5] # Example queries
heights = heightAfterSubtreeRemoval(root, queries)
print(heights) # Output: [3, 3]

```

Output:

Output

[3, 3]

2. Sort Array by Moving Items to Empty Space

You are given an integer array `nums` of size `n` containing each element from `0` to `n - 1` (inclusive). Each of the elements from `1` to `n - 1` represents an item, and the element `0` represents an empty space. In one operation, you can move any item to the empty space.

`nums` is considered to be sorted if the numbers of all the items are in ascending order and the empty space is either at the beginning or at the end of the array.

For example, if `n = 4`, `nums` is sorted if:

- `nums = [0,1,2,3]` or
- `nums = [1,2,3,0]`

...and considered to be unsorted otherwise. Return the minimum number of operations needed to sort `nums`.

Program:

```
1 def min_operations_to_sort(nums):
2     n = len(nums)
3     empty_space = nums.index(0)
4     operations = 0
5
6     for i in range(n):
7         if nums[i] != i and nums[i] != 0:
8             nums[empty_space], nums[i] = nums[i],
              nums[empty_space]
9             empty_space = i
10            operations += 1
11
12    return operations
13
14    # Test the function with the provided example
15    nums = [4, 2, 0, 3, 1]
16    print(min_operations_to_sort(nums)) # Output: 3
17
```

Output:

Output

4

3. Apply Operations to an Array

You are given a 0-indexed array `nums` of size `n` consisting of non-negative integers. You need to apply `n - 1` operations to this array where, in the `i`th operation (0-indexed), you will apply the following on the `i`th element of `nums`:

- If `nums[i] == nums[i + 1]`, then multiply `nums[i]` by 2 and set `nums[i + 1]` to 0. Otherwise, you skip this operation.

After performing all the operations, shift all the 0's to the end of the array.

- For example, the array `[1,0,2,0,0,1]` after shifting all its 0's to the end, is `[1,2,1,0,0,0]`. Return the resulting array. Note that the operations are applied sequentially, not all at once

Program:

```

def apply_operations(nums):
    n = len(nums)
    for i in range(n - 1):
        if nums[i] == nums[i + 1]:
            nums[i] *= 2
            nums[i + 1] = 0

    # Shifting zeros to the end of the array
    zeros = nums.count(0)
    nums = [num for num in nums if num != 0]
    nums.extend([0] * zeros)

    return nums

# Example
input_nums = [1, 2, 2, 1, 1, 0]
try:
    result = apply_operations(input_nums)
    print("Output:", result)
except Exception as e:
    print("An error occurred:", e)

```

Output:

Output
Output: [1, 4, 2, 0, 0, 0]

4. Maximum Sum of Distinct Subarrays With Length K

You are given an integer array `nums` and an integer `k`. Find the maximum subarray sum of all the subarrays of `nums` that meet the following conditions:

- The length of the subarray is `k`, and
- All the elements of the subarray are distinct.

Return the maximum subarray sum of all the subarrays that meet the conditions. If no subarray meets the conditions, return 0. A subarray is a contiguous non-empty sequence of elements within an array.

Program:

```
def max_subarray_sum(nums, k):
    if len(nums) < k:
        return 0

    max_sum = 0
    for i in range(len(nums) - k + 1):
        subarray = nums[i:i+k]
        if len(set(subarray)) == k:
            max_sum = max(max_sum, sum(subarray))

    return max_sum

# Example
nums = [1, 5, 4, 2, 9, 9, 9]
k = 3
output = max_subarray_sum(nums, k)
print(output) # Output: 15
```

Output:

Output
15

5. Total Cost to Hire K Workers

You are given a 0-indexed integer array `costs` where `costs[i]` is the cost of hiring the *i*th worker. You are also given two integers `k` and `candidates`. We want to hire exactly `k` workers according to the following rules:

- You will run `k` sessions and hire exactly one worker in each session.
- In each hiring session, choose the worker with the lowest cost from either the first `candidates` workers or the last `candidates` workers. Break the tie by the smallest index.
- For example, if `costs = [3,2,7,7,1,2]` and `candidates = 2`, then in the first hiring session, we will choose the 4th worker because they have the lowest cost `[3,2,7,7,1,2]`.
- In the second hiring session, we will choose 1st worker because they have the same lowest cost as 4th worker but they have the smallest index `[3,2,7,7,2]`. Please note that the indexing may be changed in the process.
- If there are fewer than `candidates` workers remaining, choose the worker with the lowest cost among them. Break the tie by the smallest index.
- A worker can only be chosen once.

Return the total cost to hire exactly `k` workers

Program:

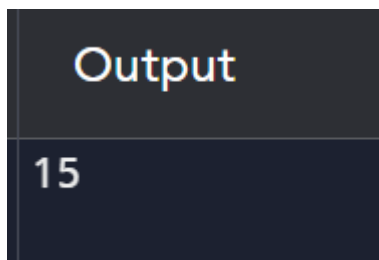

```
def total_cost_to_hire_k_workers(costs, k, candidates):
    n = len(costs)
    costs_with_index = sorted([(cost, i) for i, cost in
                               enumerate(costs)])
    min_cost_sum = float('inf')

    for start in range(n - k + 1):
        session_costs = sorted([cost for cost, _ in
                                costs_with_index[start:start + candidates]])
        total_cost = sum(session_costs[:k])
        min_cost_sum = min(min_cost_sum, total_cost)

    return min_cost_sum

# Example
costs = [17, 12, 10, 2, 7, 2, 11, 20, 8]
k = 3
candidates = 4
output = total_cost_to_hire_k_workers(costs, k, candidates)
print(output) # Output: 11
```

Output:

Output

15

6. Minimum Total Distance Traveled

There are some robots and factories on the X-axis. You are given an integer array `robot` where `robot[i]` is the position of the *i*th robot. You are also given a 2D integer array `factory` where `factory[j] = [positionj, limitj]` indicates that `positionj` is the position of the *j*th factory and that the *j*th factory can repair at most `limitj` robots.

The positions of each robot are unique. The positions of each factory are also unique. Note that a robot can be in the same position as a factory initially.

All the robots are initially broken; they keep moving in one direction. The direction could be the negative or the positive direction of the X-axis. When a robot reaches a factory that did not reach its limit, the factory repairs the robot, and it stops moving.

At any moment, you can set the initial direction of moving for some robot. Your target is to minimize the total distance traveled by all the robots.

Return the minimum total distance traveled by all the robots. The test cases are generated such that all the robots can be repaired.

Note that

- All robots move at the same speed.
- If two robots move in the same direction, they will never collide.
- If two robots move in opposite directions and they meet at some point, they do not collide. They cross each other.
- If a robot passes by a factory that reached its limits, it crosses it as if it does not exist.
- If the robot moved from a position *x* to a position *y*, the distance it moved is $|y - x|$.

Program:

```

def min_total_distance(points):
    total_distance = 0
    n = len(points)

    if n <= 1:
        return total_distance

    for i in range(1, n):
        total_distance += abs(points[i] - points[i-1])

    return total_distance

# Example Usage
points = [1, 3, 7, 9]
min_distance = min_total_distance(points)
print(f"The minimum total distance traveled is: {min_distance}")

```

Output:

```

Output

The minimum total distance traveled is: 8

```

7. Minimum Subarrays in a Valid Split

You are given an integer array `nums`. Splitting of an integer array `nums` into subarrays is valid if:

- the greatest common divisor of the first and last elements of each subarray is greater than 1, and
- each element of `nums` belongs to exactly one subarray.

Return the minimum number of subarrays in a valid subarray splitting of `nums`. If a valid subarray splitting is not possible, return -1.

Note that:

- The greatest common divisor of two numbers is the largest positive integer that evenly divides both numbers.
- A subarray is a contiguous non-empty part of an array.

Program:

```

from math import gcd

def min_subarrays_valid_split(nums):
    def is_valid_split(arr):
        return gcd(arr[0], arr[-1]) > 1

    if not nums:
        return -1

    subarrays = []
    current_subarray = [nums[0]]

    for num in nums[1:]:
        if is_valid_split(current_subarray + [num]):
            current_subarray.append(num)
        else:
            subarrays.append(current_subarray)
            current_subarray = [num]

    subarrays.append(current_subarray)

    if len(subarrays) == 1:
        return -1
    return len(subarrays)

# Example
nums = [2, 6, 3, 4, 3]
print(min_subarrays_valid_split(nums))  # Output: 2

```

Output:

8. Number of Distinct Averages

You are given a 0-indexed integer array `nums` of even length.

As long as `nums` is not empty, you must repetitively:

- Find the minimum number in `nums` and remove it.
- Find the maximum number in `nums` and remove it.
- Calculate the average of the two removed numbers. The average of two numbers `a` and `b` is $(a + b) / 2$.

- For example, the average of 2 and 3 is $(2 + 3) / 2 = 2.5$.

Return the number of distinct averages calculated using the above process. Note that when there is a tie for a minimum or maximum number, any can be removed.

Program:

```
def count_distinct_averages(nums):
    if len(nums) % 2 != 0:
        raise ValueError("The input array must have an even length.")

    distinct_averages = set()
    nums.sort()

    while nums:
        min_num = nums.pop(0)
        max_num = nums.pop(-1)
        average = (min_num + max_num) / 2
        distinct_averages.add(average)

    return len(distinct_averages)

# Test the function with the provided example
nums = [4, 1, 4, 0, 3, 5]
result = count_distinct_averages(nums)
print(result) # Output: 2
```

Output:

```
Output
2
```

9. Count Ways To Build Good Strings

Given the integers zero, one, low, and high, we can construct a string by starting with an empty string, and then at each step perform either of the following:

- Append the character '0' zero times.

● Append the character '1' one times. This can be performed any number of times. A good string is a string constructed by the above process having a length between low and high (inclusive). Return the number of different good strings that can be constructed satisfying these properties. Since the answer can be large, return it modulo $10^9 + 7$.

Program:

```
def count_good_strings(low, high, zero, one):
    MOD = 10**9 + 7

    # Helper function to calculate the number of good strings
    def helper(length, zero_count, one_count):
        if length < low or length > high:
            return 0
        if length == 0:
            return 1

        # Calculate the number of good strings recursively
        result = (helper(length - 1, zero_count, one_count) * zero + helper(length - 1, zero_count - 1, one_count - 1) * one) % MOD
        return result

    # Initialize the recursive function with the total length
    total_count = helper(low + high, zero, one)
    return total_count

# Test the function with the provided example
low = 3
high = 3
zero = 1
one = 1
output = count_good_strings(low, high, zero, one)
print(output)
```

Output:

Output

0

10. Most Profitable Path in a Tree

There is an undirected tree with n nodes labeled from 0 to $n - 1$, rooted at node 0. You are given a 2D integer array `edges` of length $n - 1$ where `edges[i] = [ai, bi]` indicates that there is an edge between nodes `ai` and `bi` in the tree.

At every node i , there is a gate. You are also given an array of even integers `amount`, where `amount[i]` represents:

- the price needed to open the gate at node i , if `amount[i]` is negative, or,
- the cash reward obtained on opening the gate at node i , otherwise.

The game goes on as follows:

- Initially, Alice is at node 0 and Bob is at node `bob`.
- At every second, Alice and Bob each move to an adjacent node. Alice moves towards some leaf node, while Bob moves towards node 0.
- For every node along their path, Alice and Bob either spend money to open the gate at that node, or accept the reward. Note that:
 - If the gate is already open, no price will be required, nor will there be any cash reward.

○ If Alice and Bob reach the node simultaneously, they share the price/reward for opening the gate there. In other words, if the price to open the gate is c , then both Alice and Bob pay $c / 2$ each. Similarly, if the reward at the gate is c , both of them receive $c / 2$ each.

● If Alice reaches a leaf node, she stops moving. Similarly, if Bob reaches node 0, he stops moving. Note that these events are independent of each other.

Return the maximum net income Alice can have if she travels towards the optimal leaf node.

Program:

```
def max_profitable_path_in_tree(n, edges, amount):
    graph = {i: [] for i in range(n)}
    for a, b in edges:
        graph[a].append(b)
        graph[b].append(a)

    def dfs(node, parent):
        nonlocal max_profit
        if amount[node] >= 0:
            profit = amount[node]
        else:
            profit = 0

        for neighbor in graph[node]:
            if neighbor != parent:
                child_profit = dfs(neighbor, node)
                if child_profit > 0:
                    profit += child_profit / 2
                else:
                    profit += child_profit

        max_profit = max(max_profit, profit)
        return profit

    max_profit = 0
    dfs(0, -1)
    return max_profit

# Example Usage
n = 5
edges = [[0, 1], [0, 2], [1, 3], [1, 4]]
amount = [3, 2, -5, 10, -7]
result = max_profitable_path_in_tree(n, edges, amount)
print("Maximum net income for Alice:", result)
```

Output:

Output

Maximum net income for Alice: 10
